National Aeronautics and Space Administration

Ames Research Center Moffett Field. California 94035

DISCUSSION

The equipment used to evaluate the burn/impact properties of carbon composites is shown in figure 1. The test specimen consists of carbon composites with various resin matrices which were

Figure 1.- Ames burn-impact unit.

machined to dimensions of 133 mm (5.25 in.) long and 12.7 mm (0.5 in.) wide and a thickness as received (2.3 to 3.5 mm) but preferably 3.1 mm (0.125 in.). The test specimens were weighed and mounted in the holder and a tensile load of 444.8 N (100 lb) was applied to the test specimen by compressing the spring. The burner was supplied with a mixture of air (13.1 liters/min) and propane gas (0.55 liters/min) and ignited. These values for air and propane are equivalent to 5 mol of oxygen per mol of propane which would make a nonoxidizing flame. The burner was allowed to heat up for 3 min and the temperature in the warmup position with the

door open was 927°-100° C (1700°-1850° F). A shop vacuum was attached to the exhaust port which was covered with "bridal veil" net coated with a tacky polyvinyl chloride adhesive (Rhoplex N619). The burner was rotated into position and the sample was burned for 3 min. The burner was then shut off and the specimen was allowed to cool 5 min. The specimen was then weighed and placed back in the fixture and the load of 444.8 N was applied. The specimen was then impacted at an impact velocity of 12.2 m/sec with the piston from the air cylinder. The load on the air cylinder was 0.648 MPa (94 psi). After the specimen was impacted it was removed and weighed.

The percent of fiber weight loss from impact was calculated as:

% Impact loss =
$$\frac{\text{Weight after burn - weight after Impact}}{\text{Original weight (60%)}} \times 100$$

The calculation of the char binder of the composite was made based on the temperature of the test specimen and the char yield of the resin as determined by thermogravimetric analysis. In the burn-impact procedure, the 50-mm (2-in.) diam heater was mounted at a distance of 20.0 mm (0.8125 in.) from the test specimen. Because of conductive heat flow through the test specimen, there is a resulting thermal profile across the specimen (see fig. 2). From the center to a point 12.7 mm (0.5 in.) on either side of the centerline, the maximum temperature was 750° C (1385° F). Nineteen mm (0.75 in.) on either side of the centerline, the maximum temperature was 649° C (1200° F). At a distance of 25.4 mm (1.0 in.) on either side of the centerline, the temperature was 520° C (968° F). At 38.1 mm (1.5 in.) on either side of the centerline, the maximum temperature was 427° C (800° F). Thus, if the temperature gradient, resin content (% wt), and char yield are known, the percent char binder can be calculated.

Figure 2.- Thermal profile of burn test specimen.

The theoretical char binder of the composite is calculated as:

Calculated char binder =
$$\frac{R'}{\text{Specimen weight} \times 60\%}$$

where:

$$R' = R(0.2)(Y_c750^{\circ} \text{ C}) + R(0.1)(Y_c649^{\circ} \text{ C}) + R(0.1)(Y_c520^{\circ} \text{ C}) + R(0.2)(Y_c427^{\circ} \text{ C})$$

R = Specimen weight X resin content (% weight)

In this equation the weight fraction of each temperature zone is multiplied by the char yield (table 1). The sum of the char yield for each zone is divided by 60% of the weight of the specimen to give the percent char binder. The original specimen weight is normalized to 60% because this is the portion of the specimen that is heated to a temperature above 280° C (536° F). Below that temperature, the weight loss is insignificant (5% or less).

An example of the calculated char binder for an epoxy/carbon composite with a resin content of 33.2% (wt) and the char yield at 750° C of 36%, at 649° C of 37%, at 520° C of 41%, and at 427° C of 56%, with a sample weight of 8.02 g, is 14.5%.

TABLE 1.— RESIN CHAR YIELD — THERMOGRAVI-METRIC ANALYSIS

	PERCENT CHAR YIELD			
RESIN TYPE	750°C	649°C	520° C	427°C
POLYSTRYL PYRIDINE	68	72	80	96
EPOXY	36	37	41	56
PHENOLIC - A	58	60	72	84
PHENOLIC - B	54	55	68	92
PHENOLIC - C	61	64	76	88
POLYIMIDE	55	58	72	86

TEST RESULTS

Eleven test composites were prepared using the processing conditions given in table 2. Five specimens of each were subjected to the burn/impact procedure. The resin content, resin type, fiber type, calculated char binder, and percent weight loss after burn and impact are summarized in table 3. The resins used included epoxy, phenolic, polystryl pyridine, and polyimide.

The carbon reinforcements used include unidirectional tape, satin weave, and plain weave. The samples listed in table 3 are grouped according to the type of reinforcement. The first two samples were made with unidirectional tape in a "quasi-isotropic" layup $(0, \pm 45, 90)$; the next seven samples were made with a satin weave $(T-300, 24\times24 \text{ yarn count}, 11 \text{ oz/yd}^2)$ cloth; and the last two samples were made with plain weave $(T-300, 12\times12 \text{ yarn count}, 5.5 \text{ oz/yd}^2)$ cloth. The quasi-isotropic samples had higher fiber loss (as determined by weight loss after burn and impact) than the woven samples. For example, the epoxy resin quasi-isotropic composite had fiber release of 12.6% with calculated char binder of 13.1%; the same resin on satin weave cloth had fiber release of 1.02% with char binder (cal.) of 14.5%; on a plain weave cloth sample, the fiber release was 0.9% with calculated char binder of 11.4%.

Because the majority of the samples tested was made with satin weave cloth, a comparison can be made between the different resin systems and in two cases comparing two different resin contents with the same resin type. The test results listed in table 3 are ranked according to the calculated char binder. The values for the calculated char binder are listed with the highest values at the top. The values for percent impact loss and calculated char binder are also presented in figure 3. It can be seen that the higher the char yield the lower the impact loss. Samples with the same type of resin (phenolic-2), such as S-2 and S-4, show that with higher resin content there is necessarily a higher char binder and less fiber release after burn and impact. The same results held true for the two epoxy samples (S-6 and S-7). The upper values for achieving improved fiber retention is not known, but within the resin contents employed there is a correlation between resin content and fiber release.

TABLE 2.- COMPOSITE PROCESSING

Figure 3.— Char vs impact loss after burn of satin weave composites.

CONCLUSIONS

The burn/impact chamber provides a small-scale test apparatus for determining a relative fiber-release value for burned carbon composites. The test results indicate a difference in carbon fiber release depending on the type of reinforcement used in the composite material. There was more fiber release with the quasi-isotropic composite made with unidirectional tape than with the woven fabric reinforcement. The amount of fiber release in the impact chamber after burning is coincident with the calculated char binder present.

One goal for our research effort is to reduce or eliminate the release of conductive fibers. The use of the burn/impact test chamber will assist in the evaluation of new resins and fibers.
